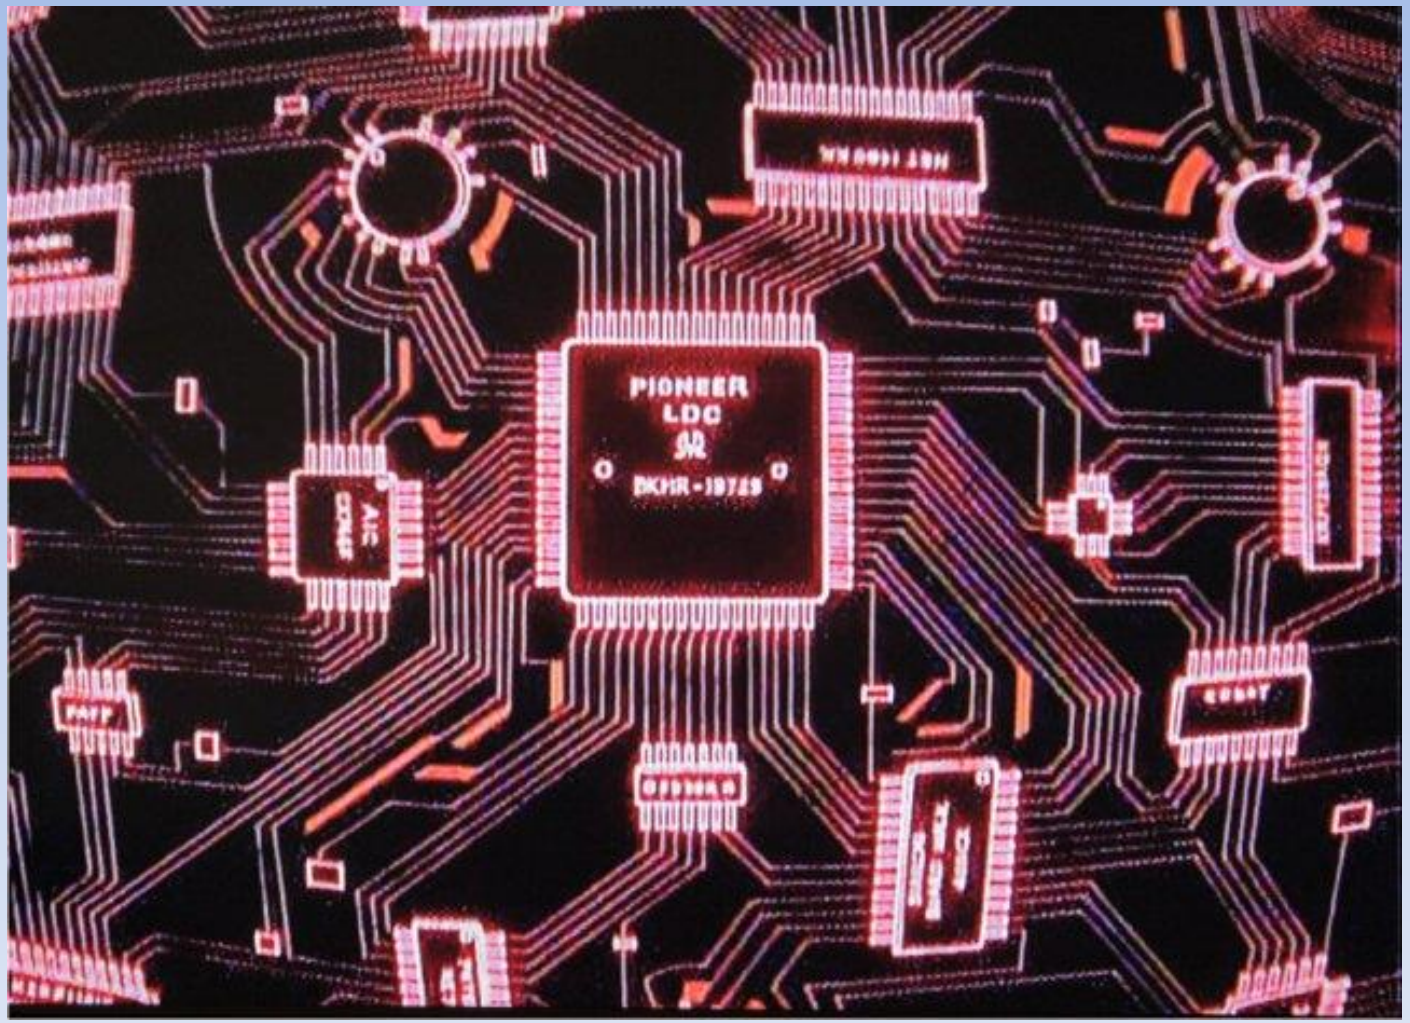
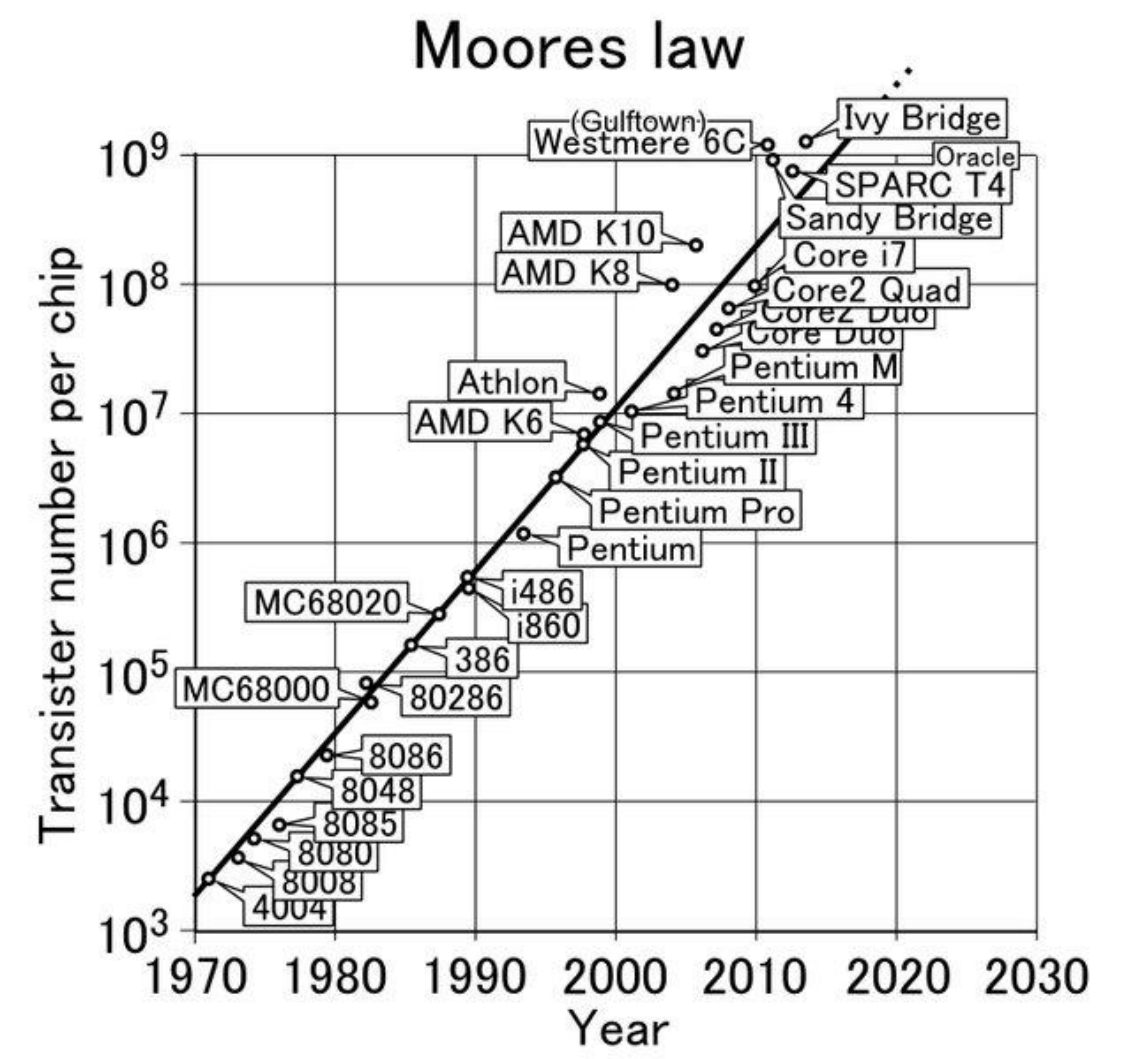
PDF version - Kick off (18 April 2016)

# 1.

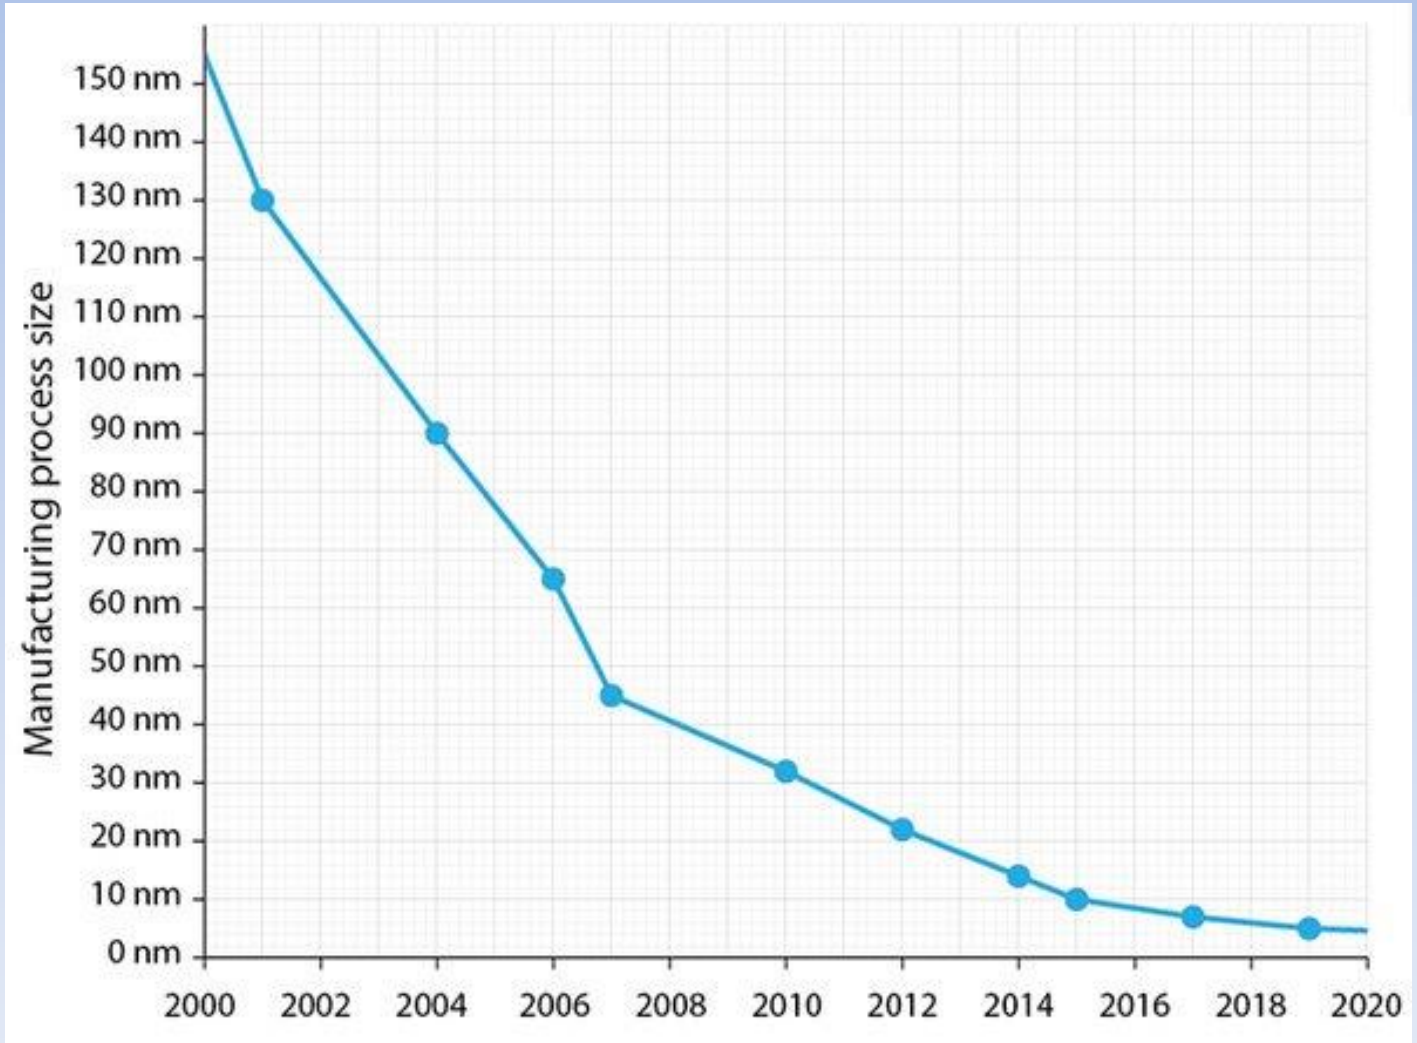
# What Is the Future of Computers?



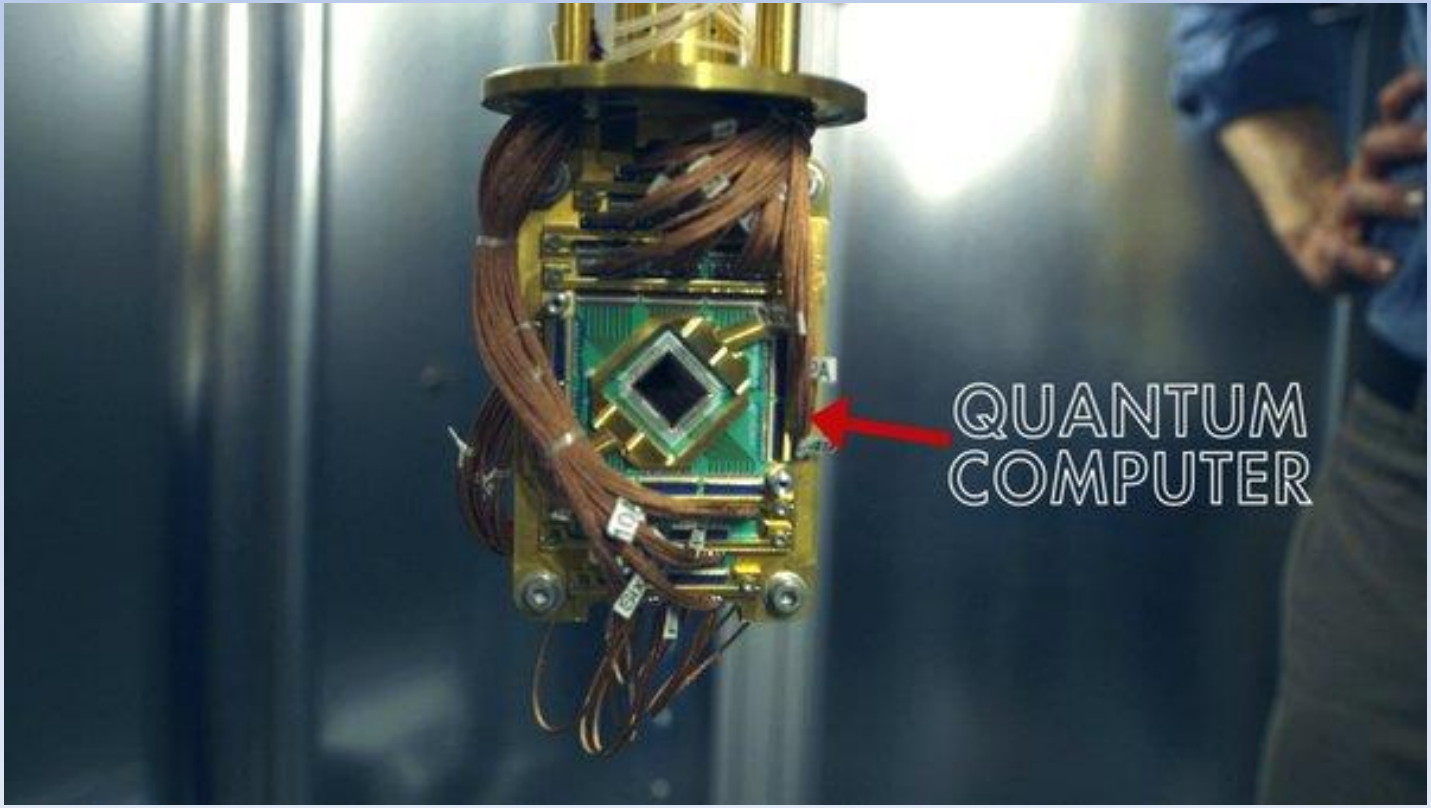
- Moore's Law states, that the number of transistors on a microprocessor double every 18 months.



- The year 2020 or 2030 will find the circuits on a microprocessor measured on an atomic scale.



- The logical next step will be to create quantum computers, which will harness the power of atoms and molecules to perform memory and processing tasks.



History

- Quantum computing was first theorized in 1981 by Paul Benioff at the Argonne National Laboratory.
- Benioff theorized about creating a quantum Turing machine.

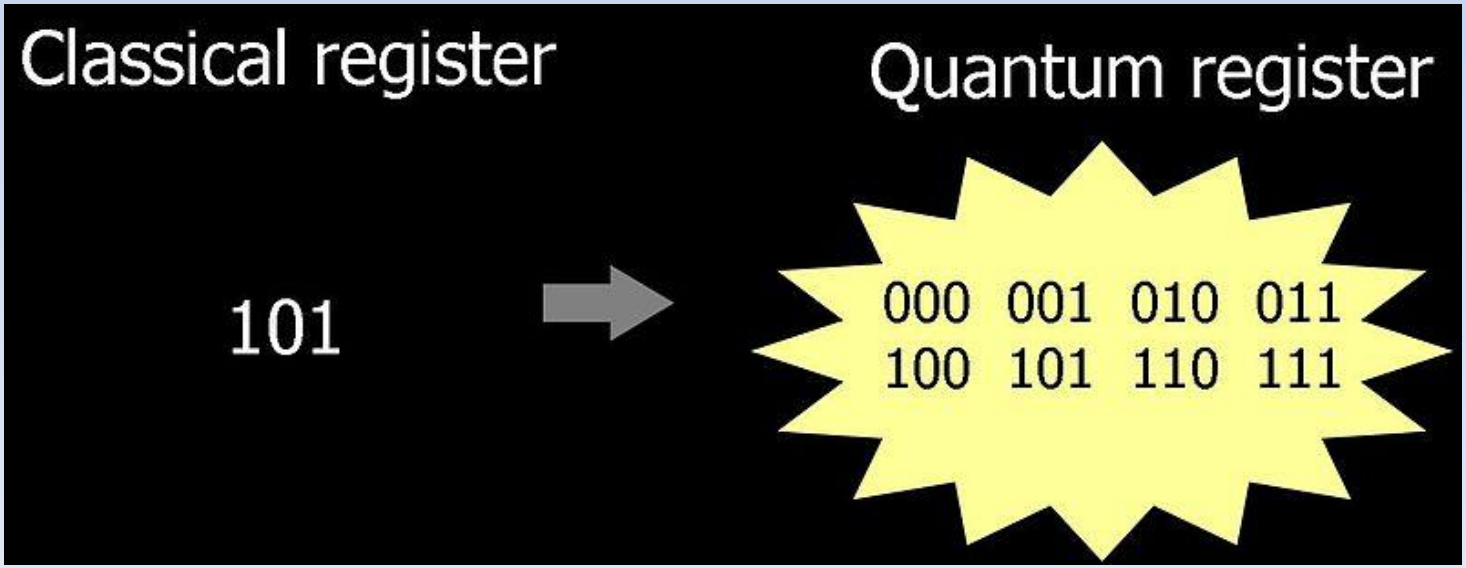
Argonne National Laboratory campus

## Concept of quantum computing

- Today's computers work by manipulating bits that exist in one of two states: a 0 or a 1.
- On the machine level, this either/or dichotomy is represented using electrical circuits which can either be closed, in which case a current flows, or open, in which case there isn't a current.

## Concept of quantum computing

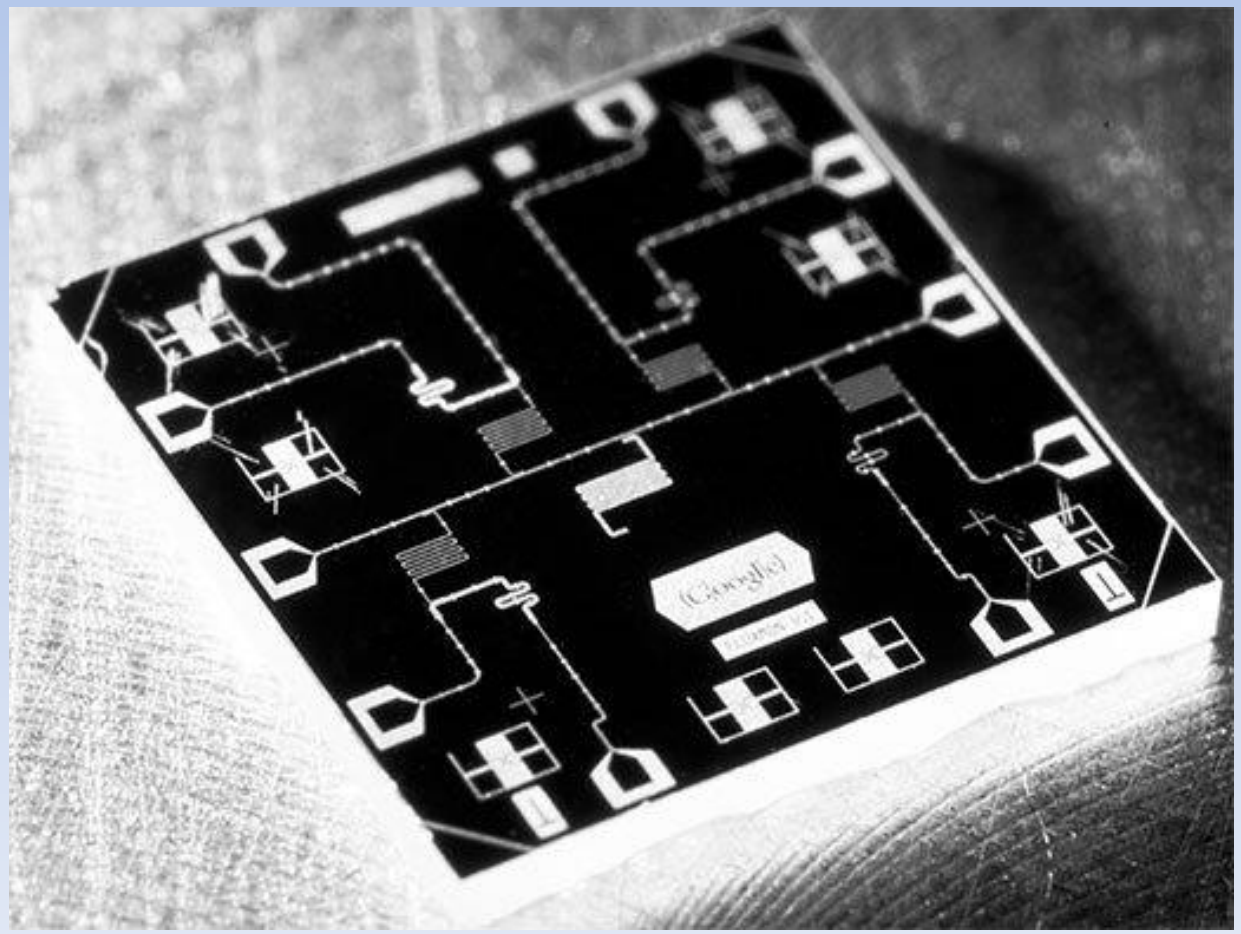
- Quantum computers aren't limited to two states; they works with particles that can be in superposition.
- Rather than representing *bits* — such particles would represent *qubits*, which can take on the value 0, or 1, or both simultaneously.



- This superposition of qubits is what gives quantum computers their inherent parallelism.
- This parallelism allows a quantum computer to work on a million computations at once, while desktop PC works on one.

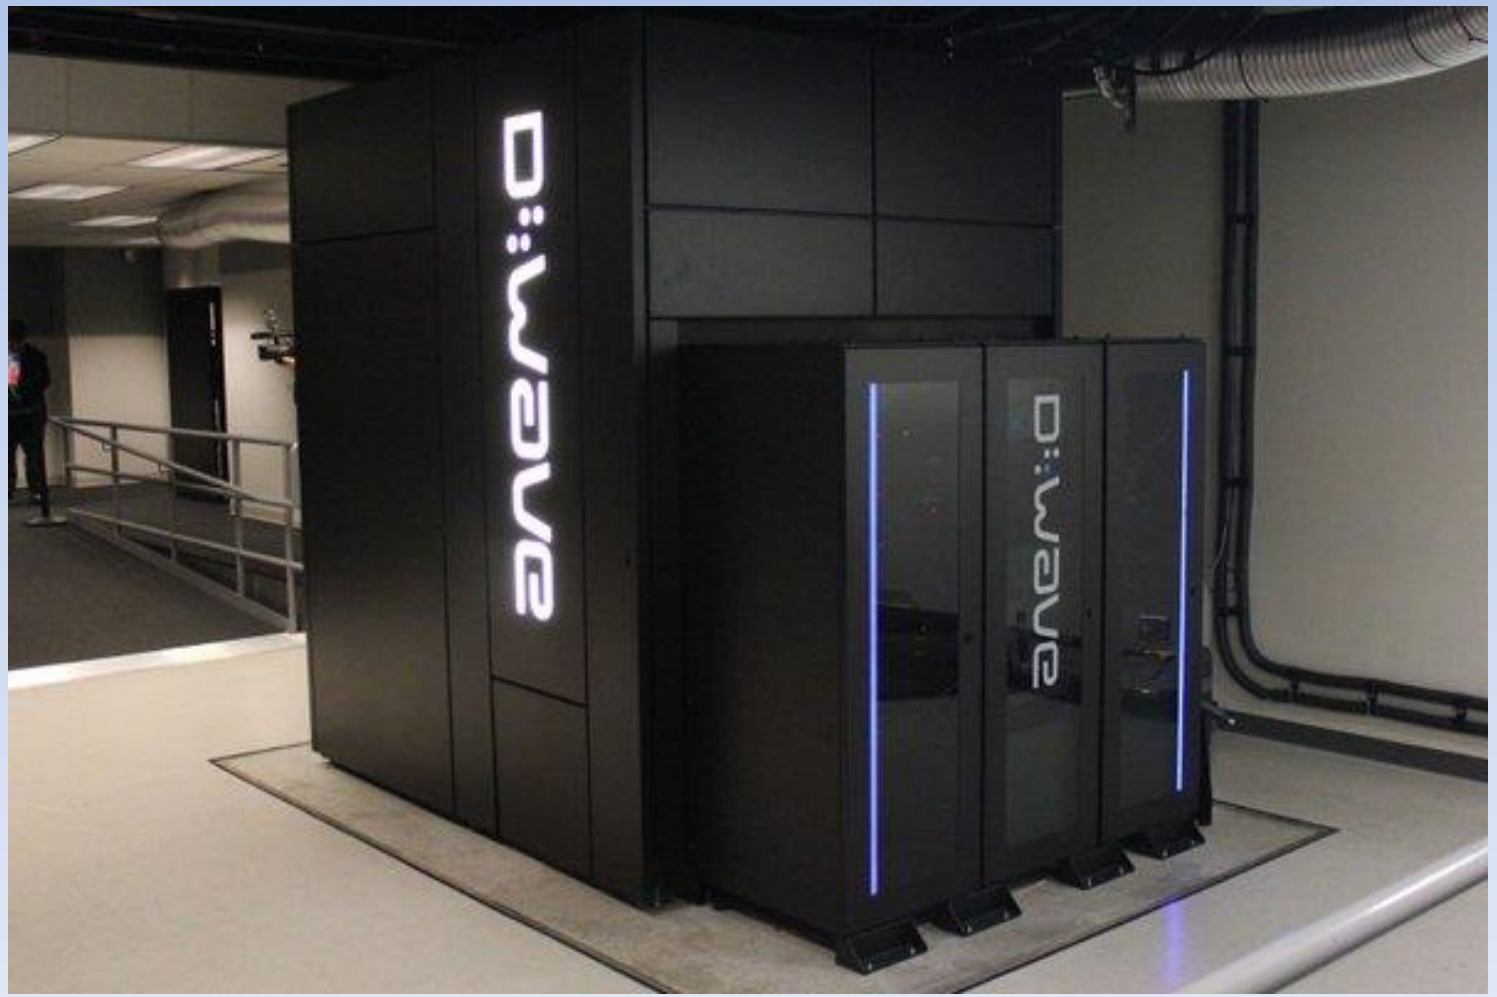
Implementation

- Scientists have already built basic quantum computers that can perform certain calculations.



Implementation

- At a NASA lab in Silicon Valley, Google is testing a D-Wave 2X quantum computer.

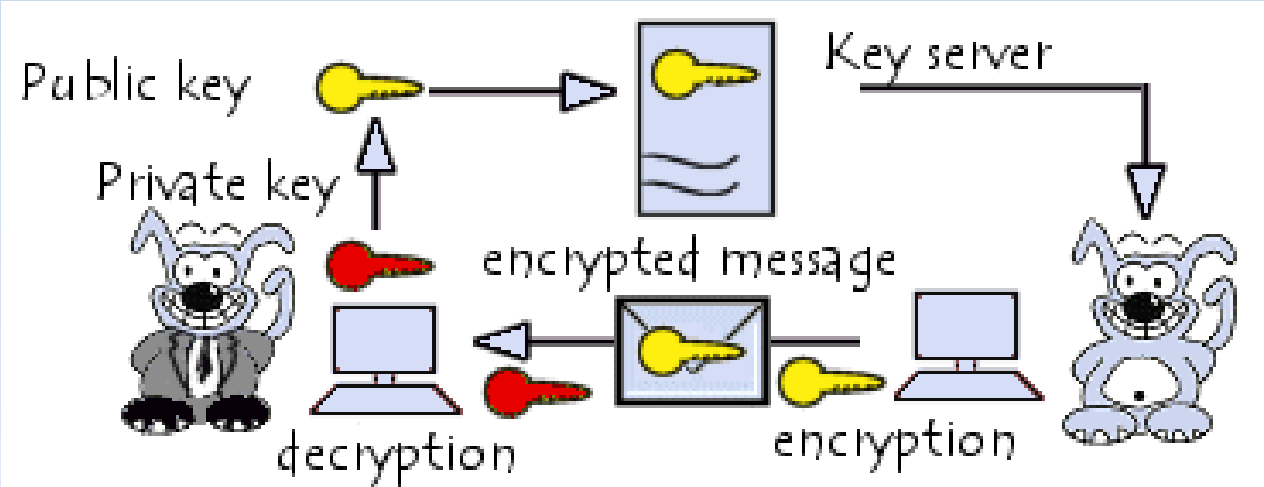


- In public-key cryptography, data is secured by math problems that are easy to solve, but hard to reverse engineer.
- While it is easy for a computer to multiply two prime numbers to produce a larger integer.

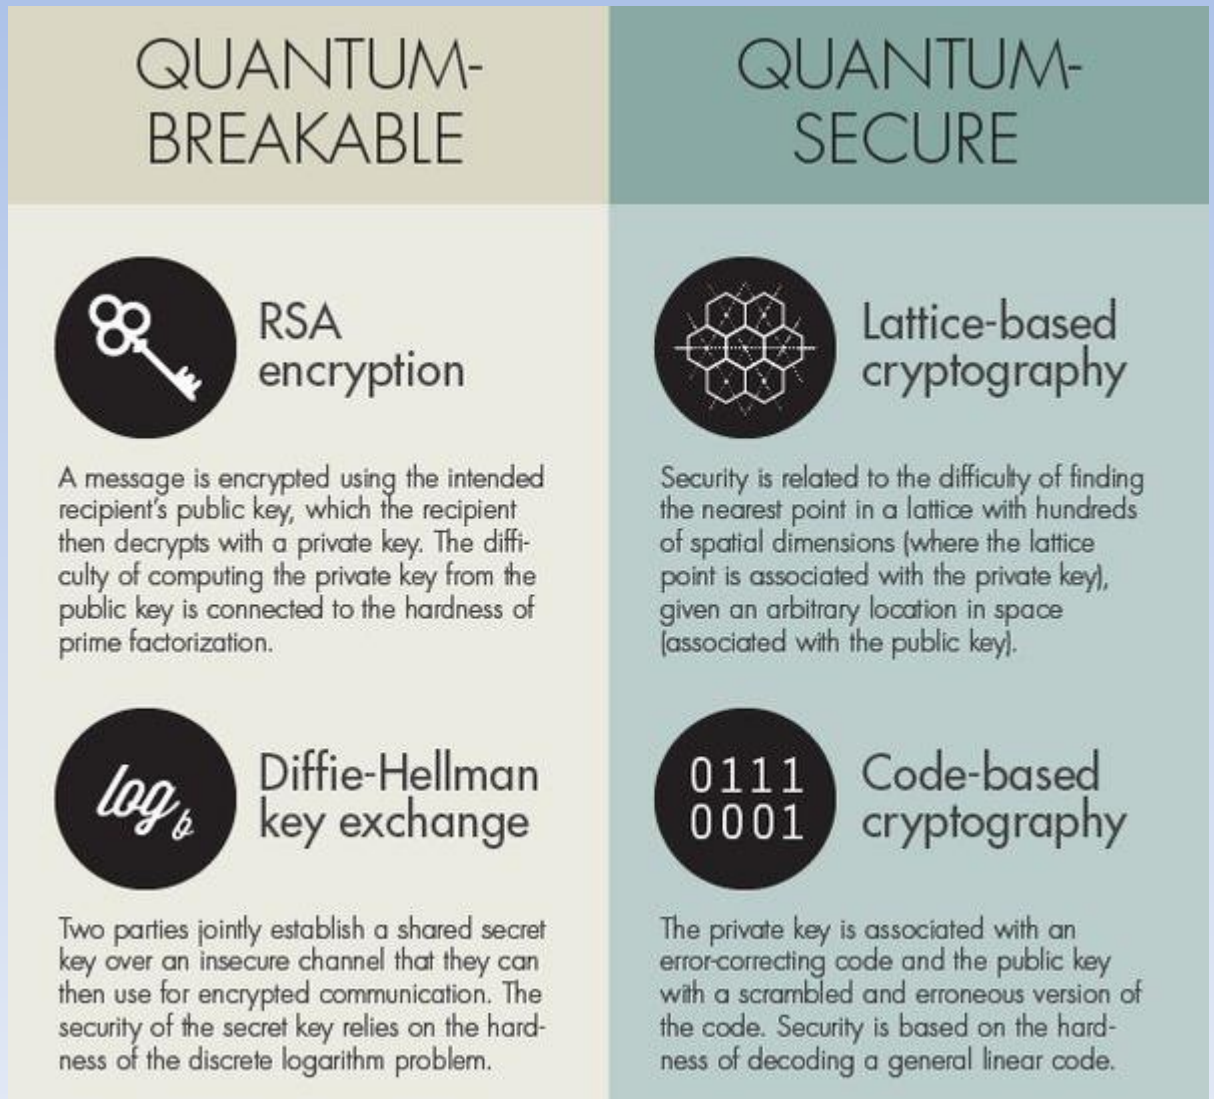
**34,141 x 81,749 = 2,790,992,609**

- It takes an impractically long time on a computer to factorize a large enough integer into its component primes.

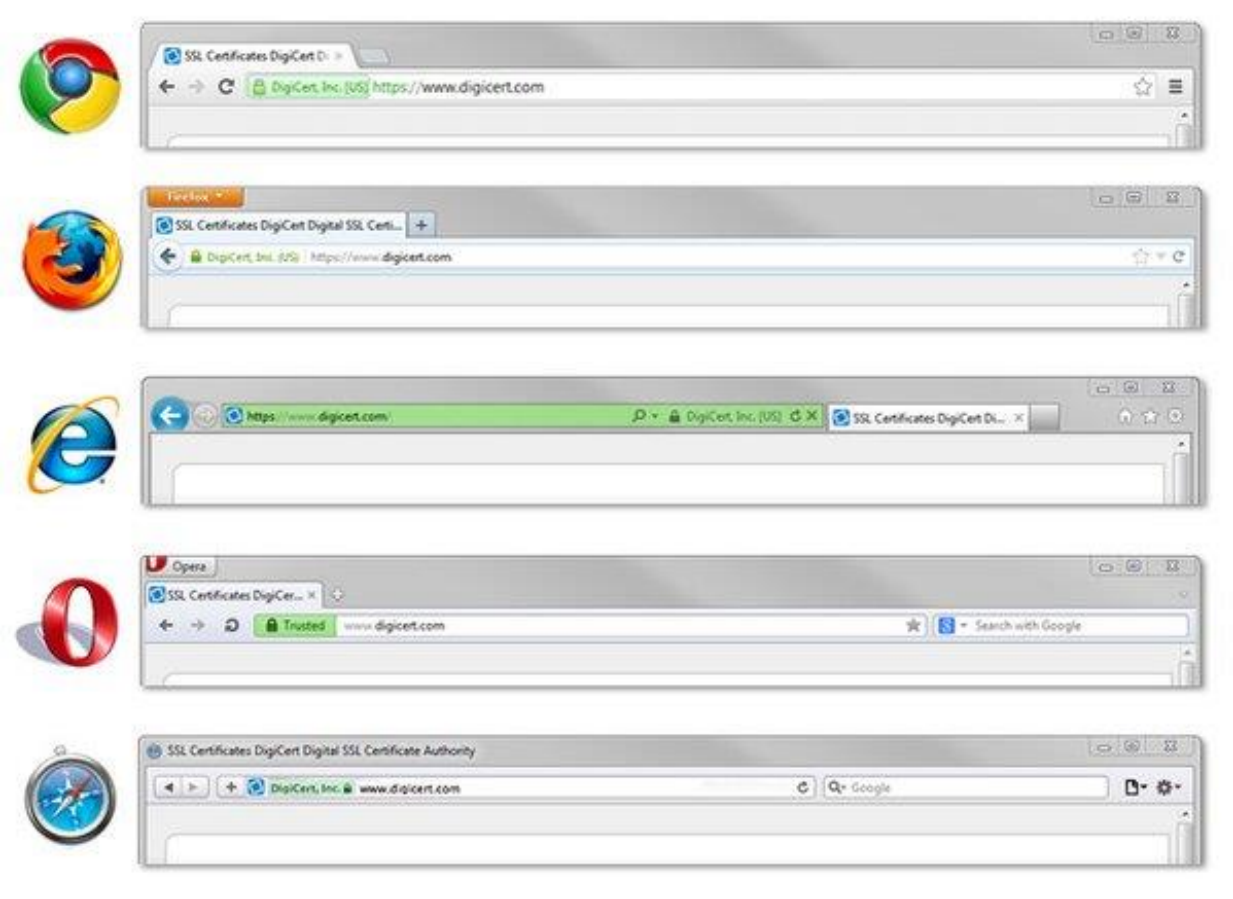
- In a crypto scheme based on prime factorization, the primes serve as a person's "private key," which is not shared.
- The product of the primes serves as the "public key," which is distributed publicly.
- When someone else uses the public key to encrypt a message, only the person in possession of the private key can decrypt it.



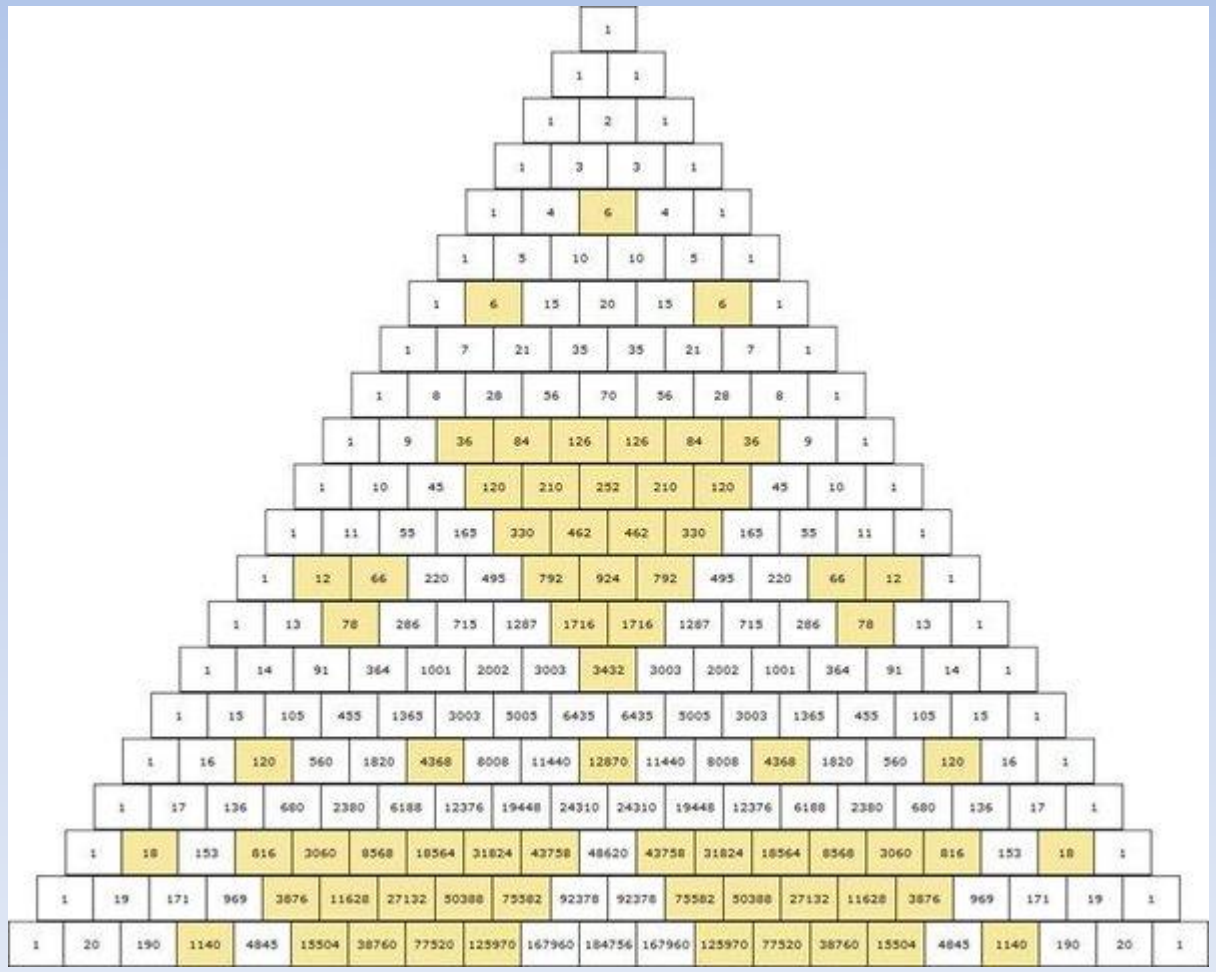
- Widely used today RSA and the Diffie-Hellman key exchange based on this principle.



- RSA(Rivest-Shamir-Adleman) algorithm is used in browsers which need to establish a secure connection.
- Every time you visit a website with a URL that begins “HTTPS,” that algorithm is used.



- A quantum computer could efficiently find prime factors for large integers.



- This ability would allow a quantum computer to decrypt many of the cryptographic systems in use today.

## Conclusion

- Quantum computing is still in early stages of development. But quantum computers will replace silicon chips in the future, just like the transistor once replaced the vacuum tube.

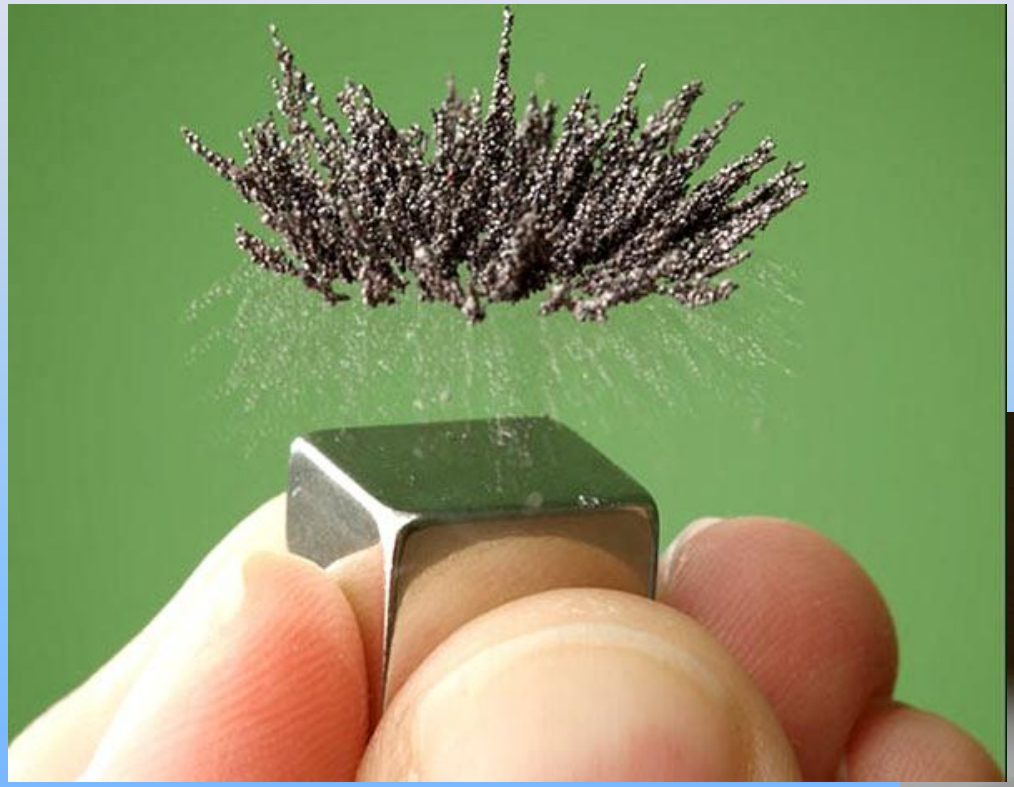
# Will the levitation become commonly used?

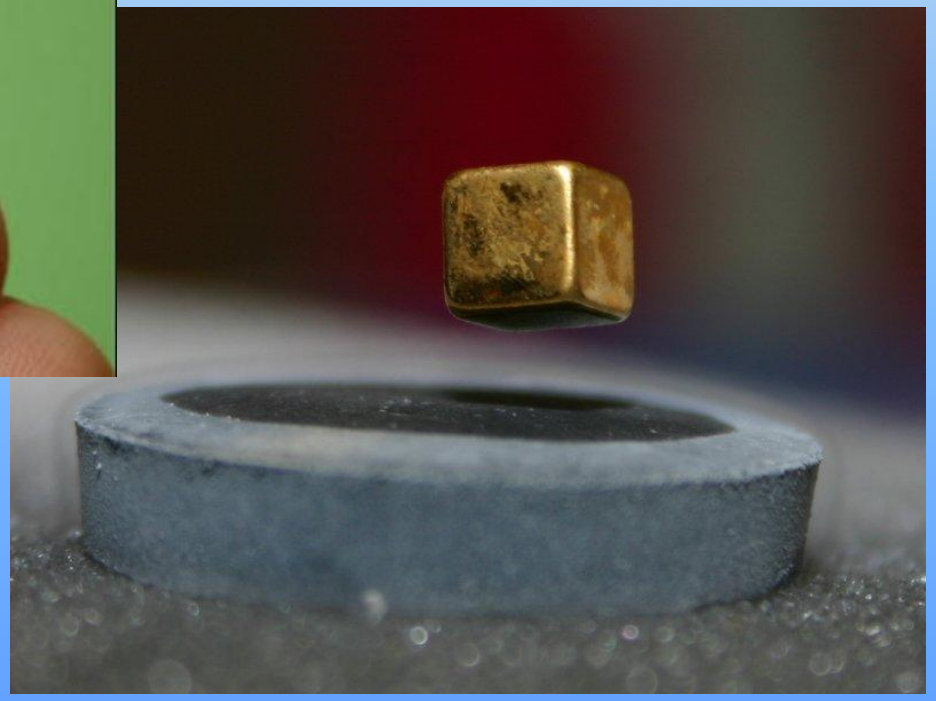
Raman Haivaronski AC-43I

**Levitation is the process by which an object is held aloft, without mechanical support, in a stable position.**

**There're a lot of types of levitation. For example, using diamagnetic levitation we can make the frogs fly. There are also such types of levitation such as acoustic levitation and optic levitation.**

**A cubical magnet levitating over a superconducting material (known as the Meissner effect),**

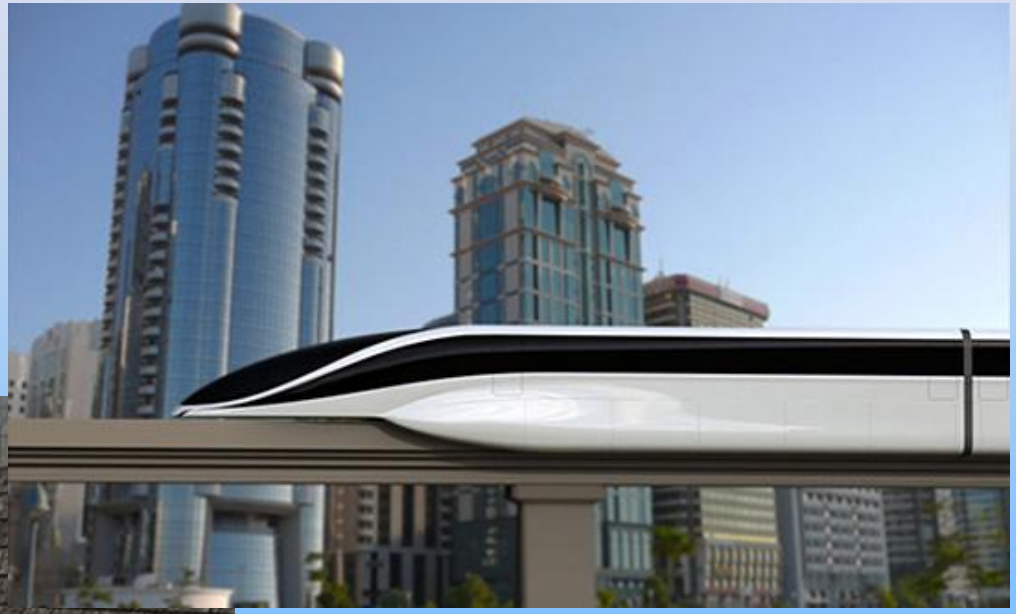




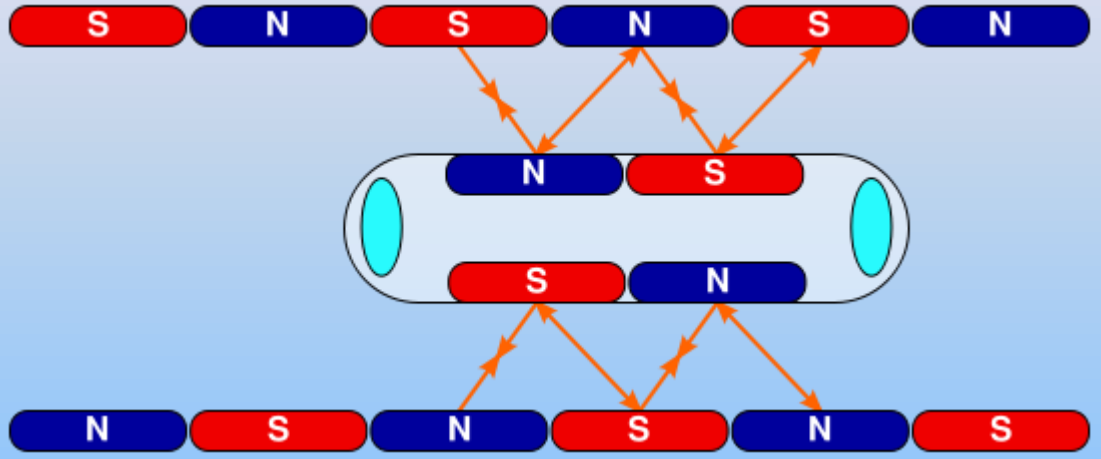
It seemed to be fantastic 20 years ago.

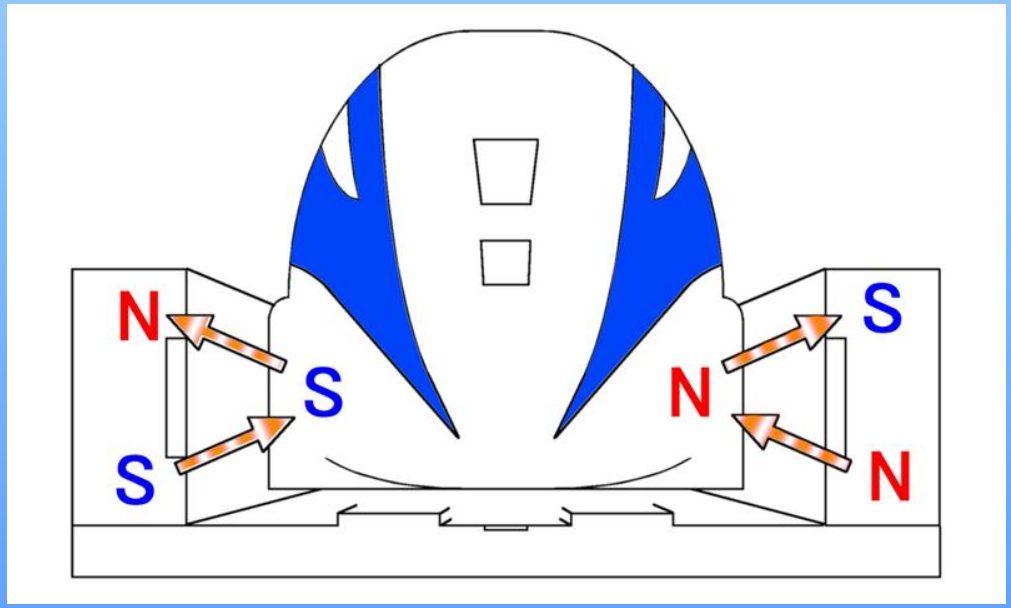
**But today it's a reality. As an example let’s take maglevs as one of the most useful inventions that use levitation.**

**Magnetic levitation is already actively used in transport systems of Japan, Germany, South Korea, China.**



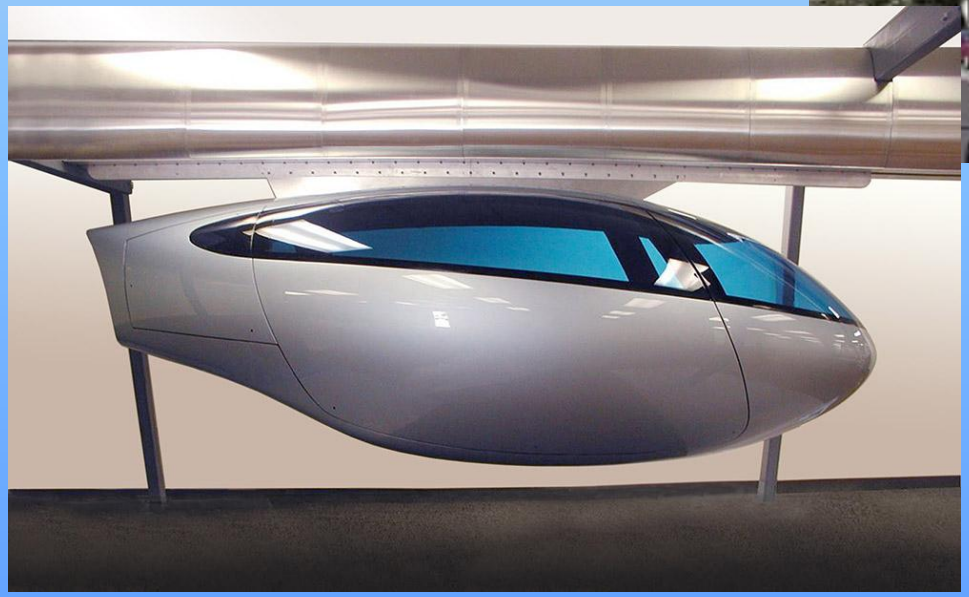
# The basic principle of magnetic poles attraction and repulsion is used.





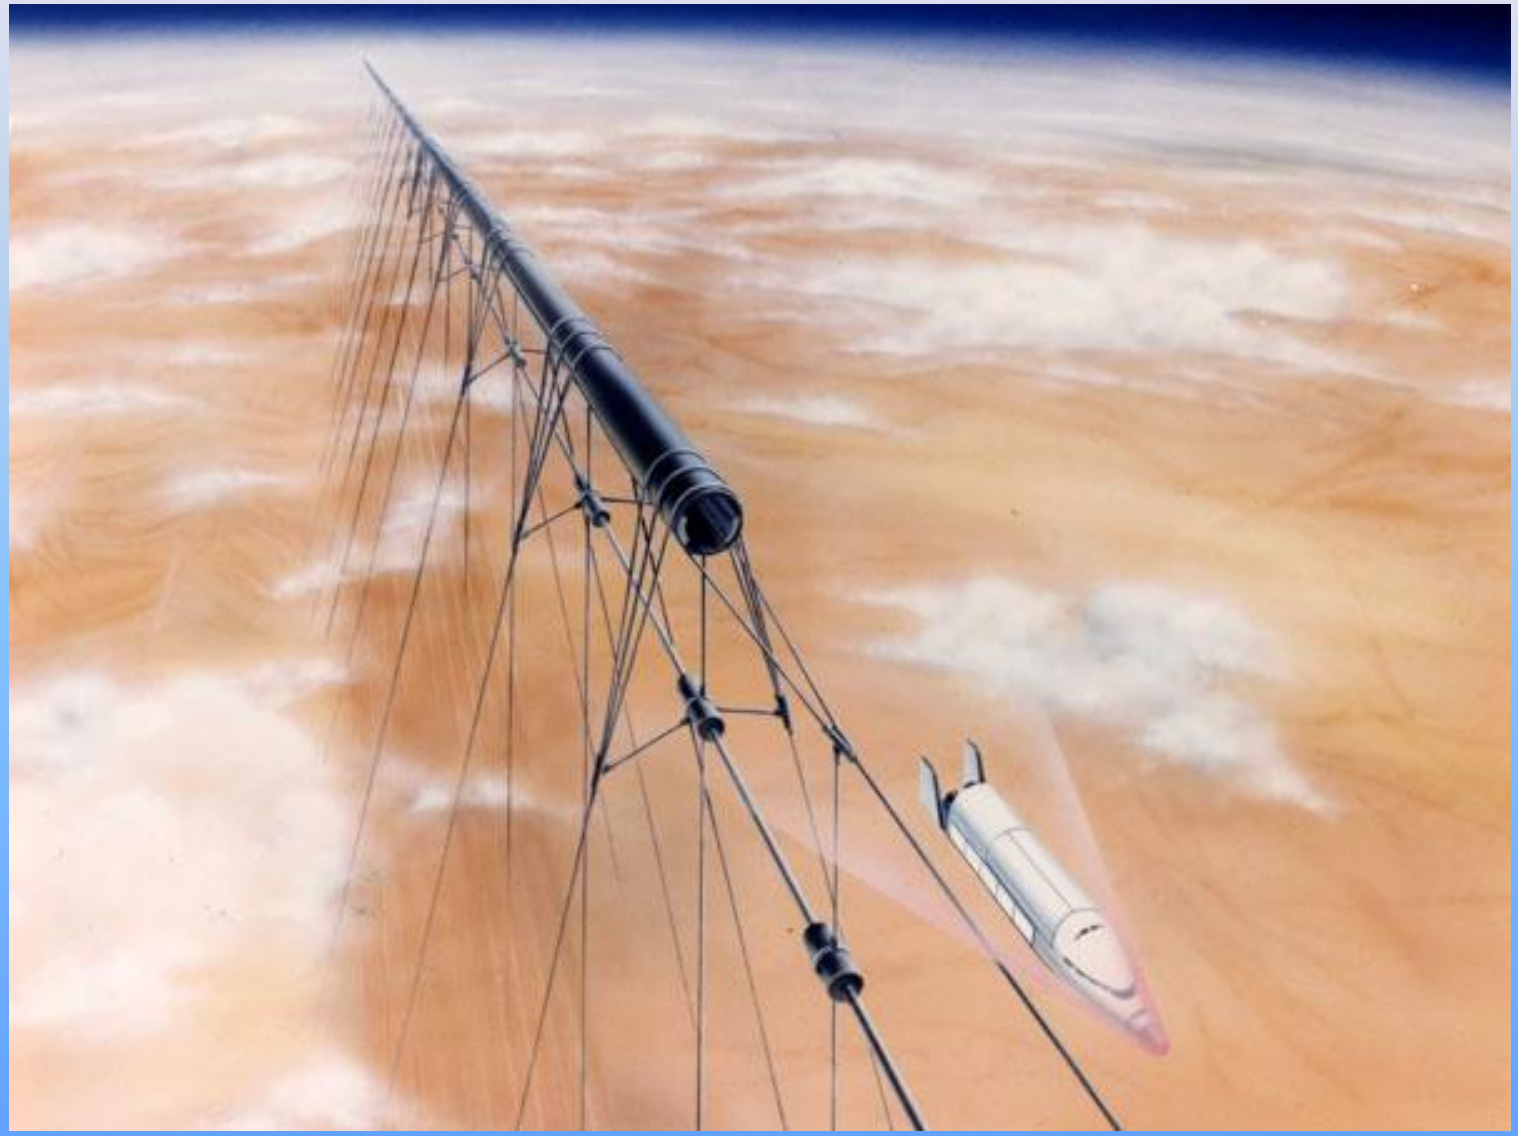
**SkyTran is a patented, high-speed, low-cost, elevated system created by NASA. The system is now being tested in Tel-Aviv, Israel.**

skyTran moves passengers in a fast, green, and economical manner. skyTran would be made safer than driving by eliminating human error.



**Magnetically levitated city is a concept of Chinese designer Wei Zhao of future human cities.**

**Maglev space launch system was researched by NASA but the cost of such track is too much ($20 billions).**



**That's how the magic of levitation is becoming a reality nowadays.**

**I want to conclude with an interesting fact: JR-Maglev MLX01 is the current Guinness record holder for train speed with the record of 603 km/h.**

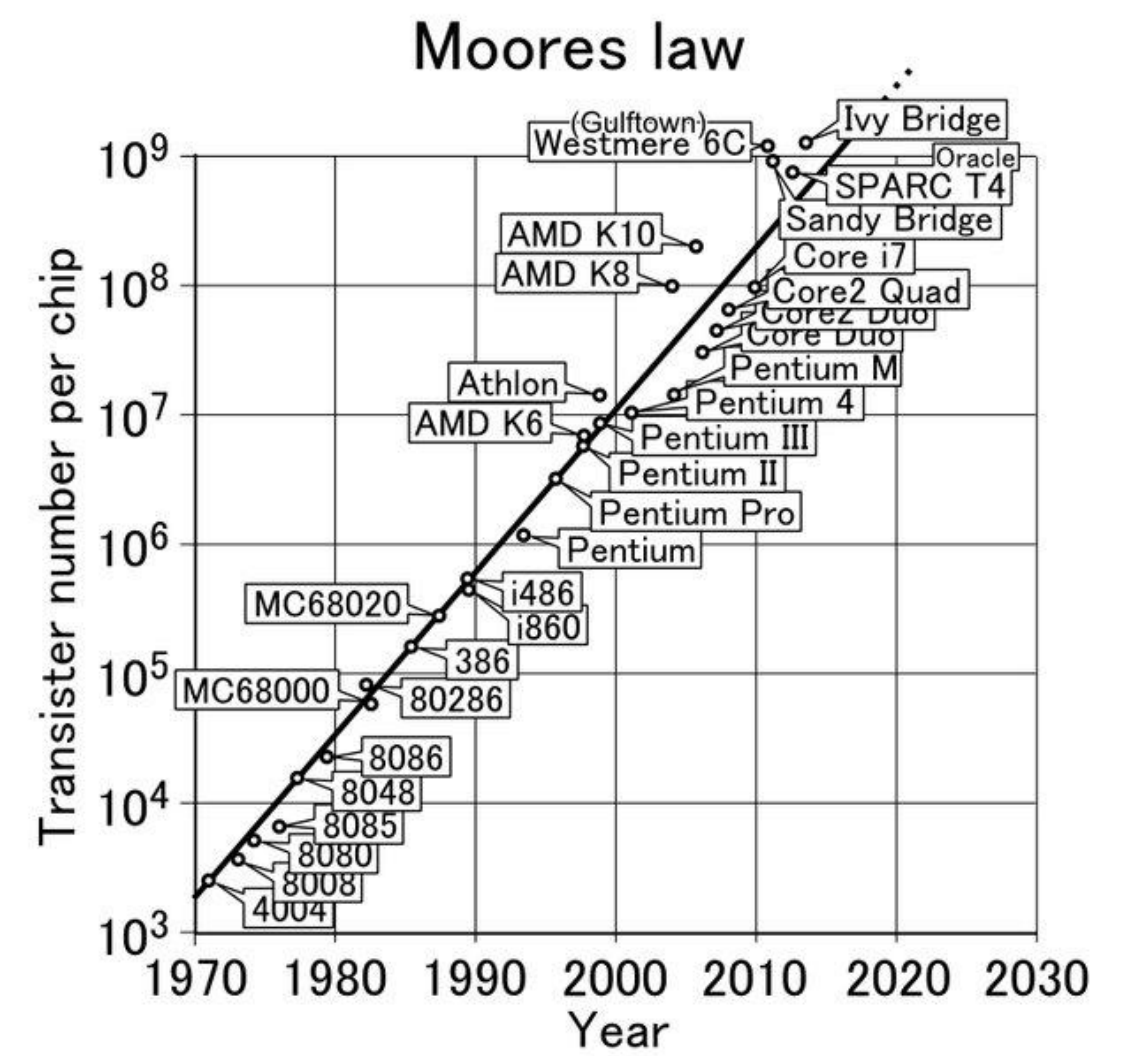
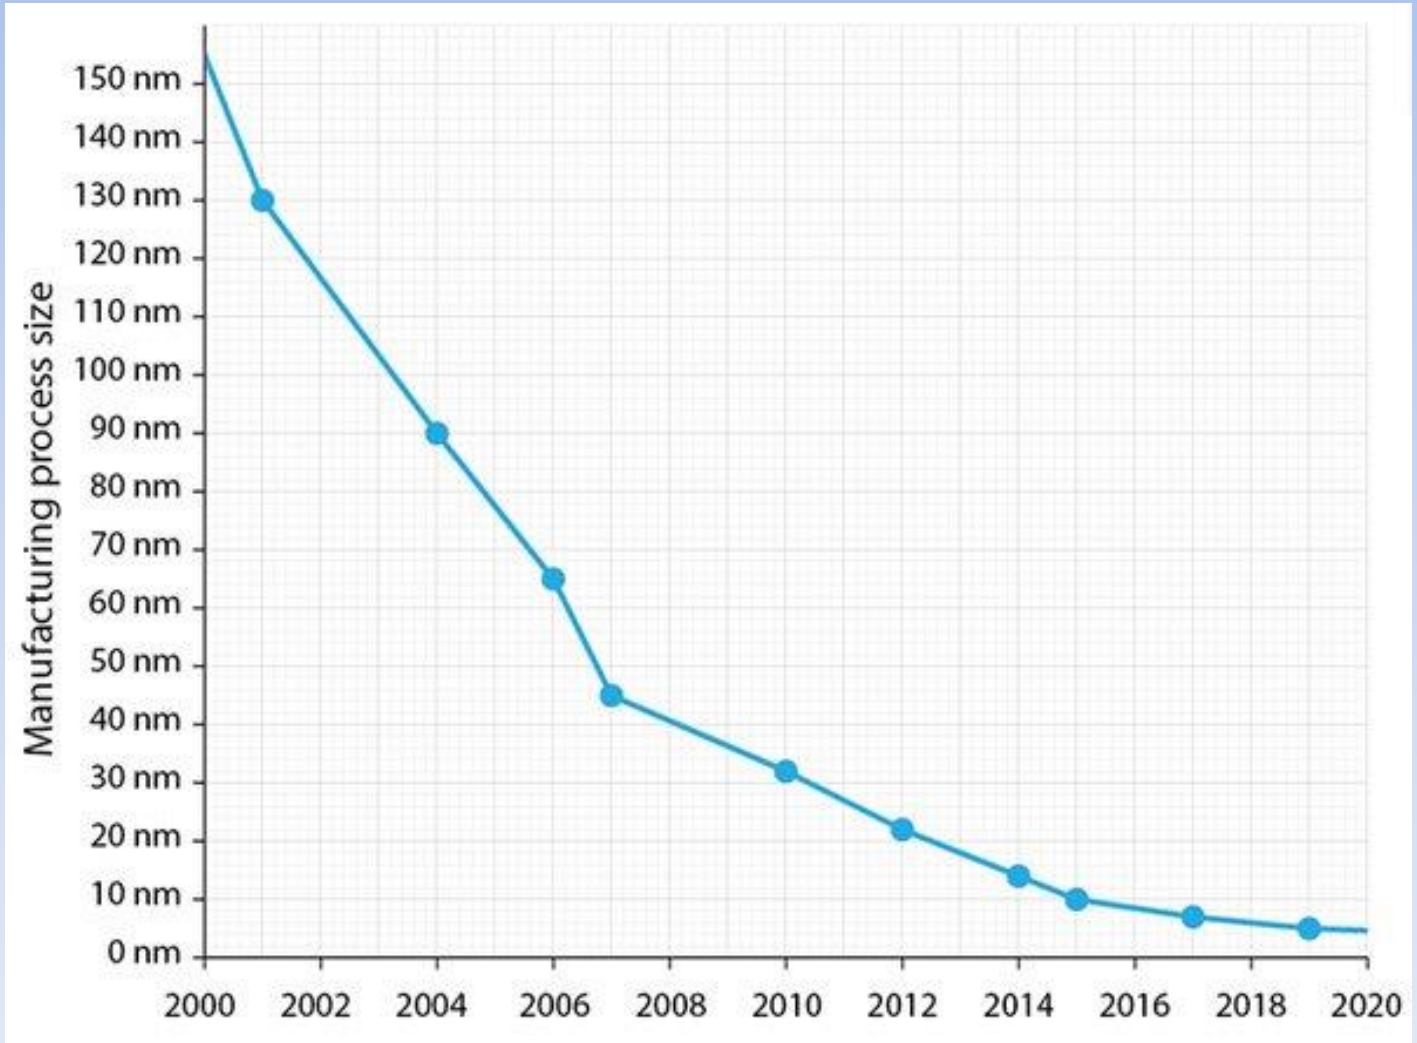
# What Is the Future of Computers?

Andrei Begel АС-43И

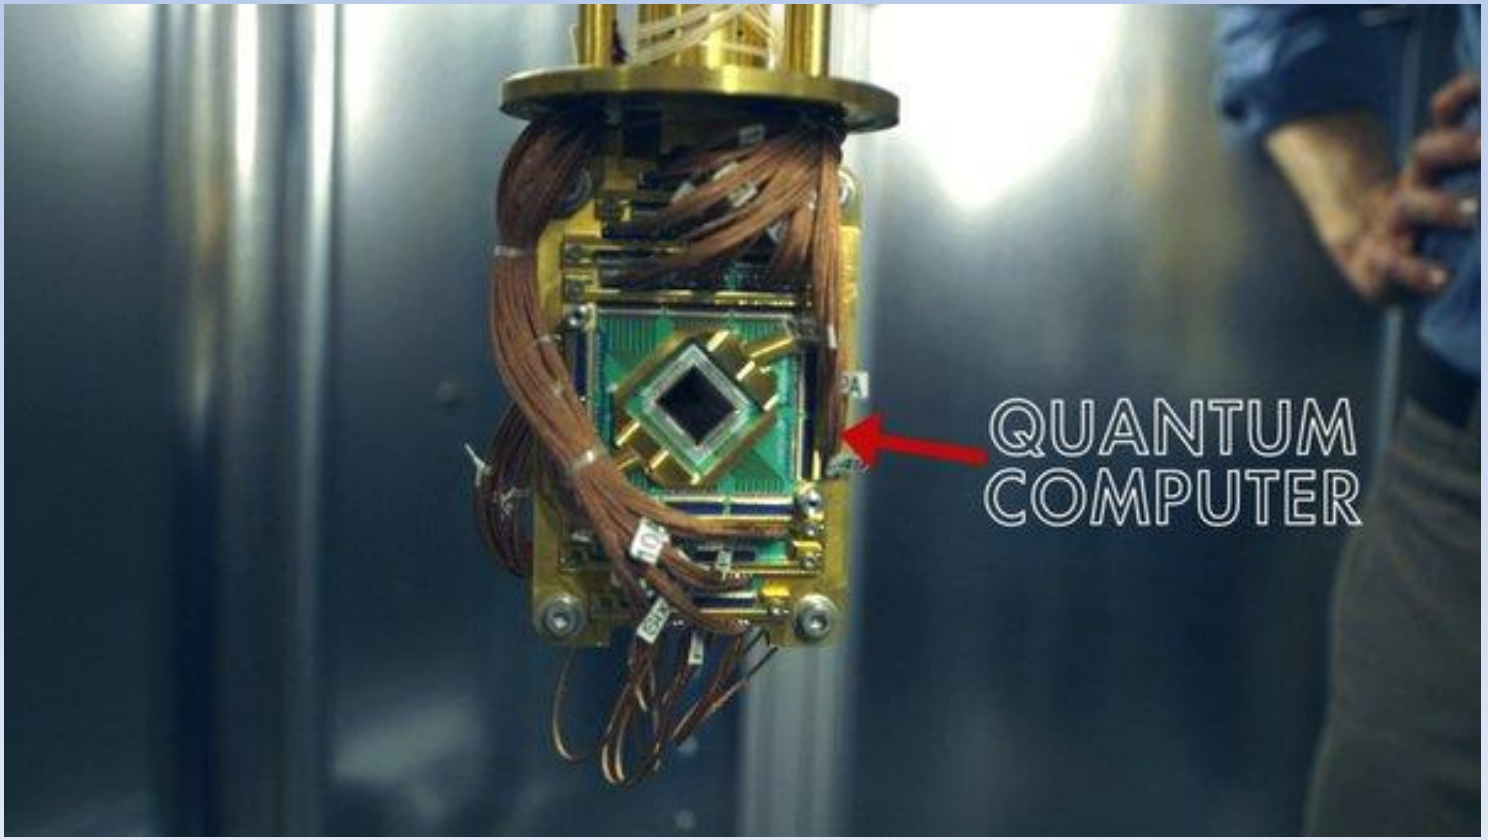
- Moore's Law states, that the number of transistors on a microprocessor double every 18 months.



- The year 2020 or 2030 will find the circuits on a microprocessor measured on an atomic scale.



- The logical next step will be to create quantum computers, which will harness the power of atoms and molecules to perform memory and processing tasks.



History

- Quantum computing was first theorized in 1981 by Paul Benioff at the Argonne National Laboratory in USA.
- Benioff theorized about creating a quantum Turing machine.

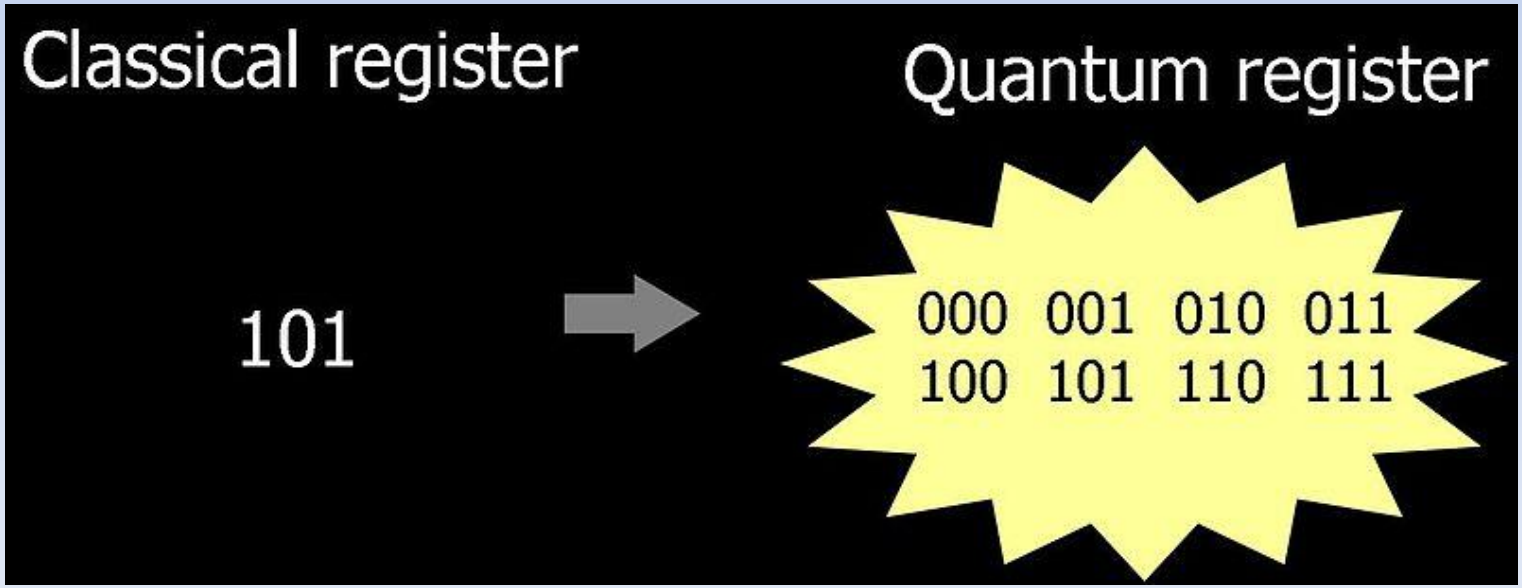
Argonne National Laboratory campus

## Concept of quantum computing

- Today's computers work by manipulating bits that exist in one of two states: 0 or 1.
- On the machine level, this either/or dichotomy is represented using electrical circuits which can either be closed, in which case a current flows, or open, in which case there isn't a current.

## Concept of quantum computing

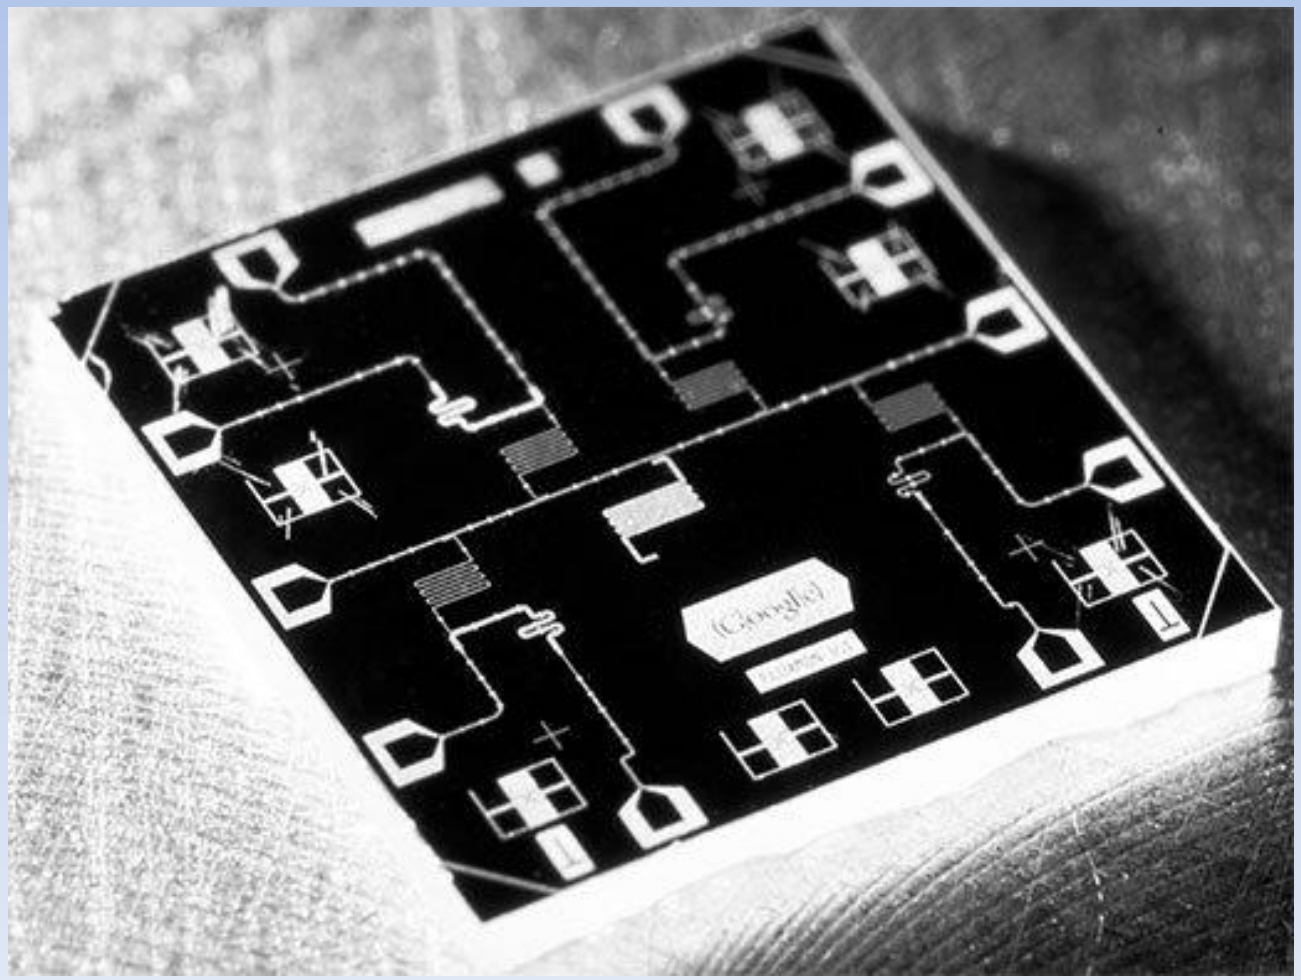
- Quantum computers aren't limited to two states; they works with particles that can be in superposition.
- Rather than representing *bits* — such particles would represent *qubits*, which can take on the value 0, or 1, or both simultaneously.



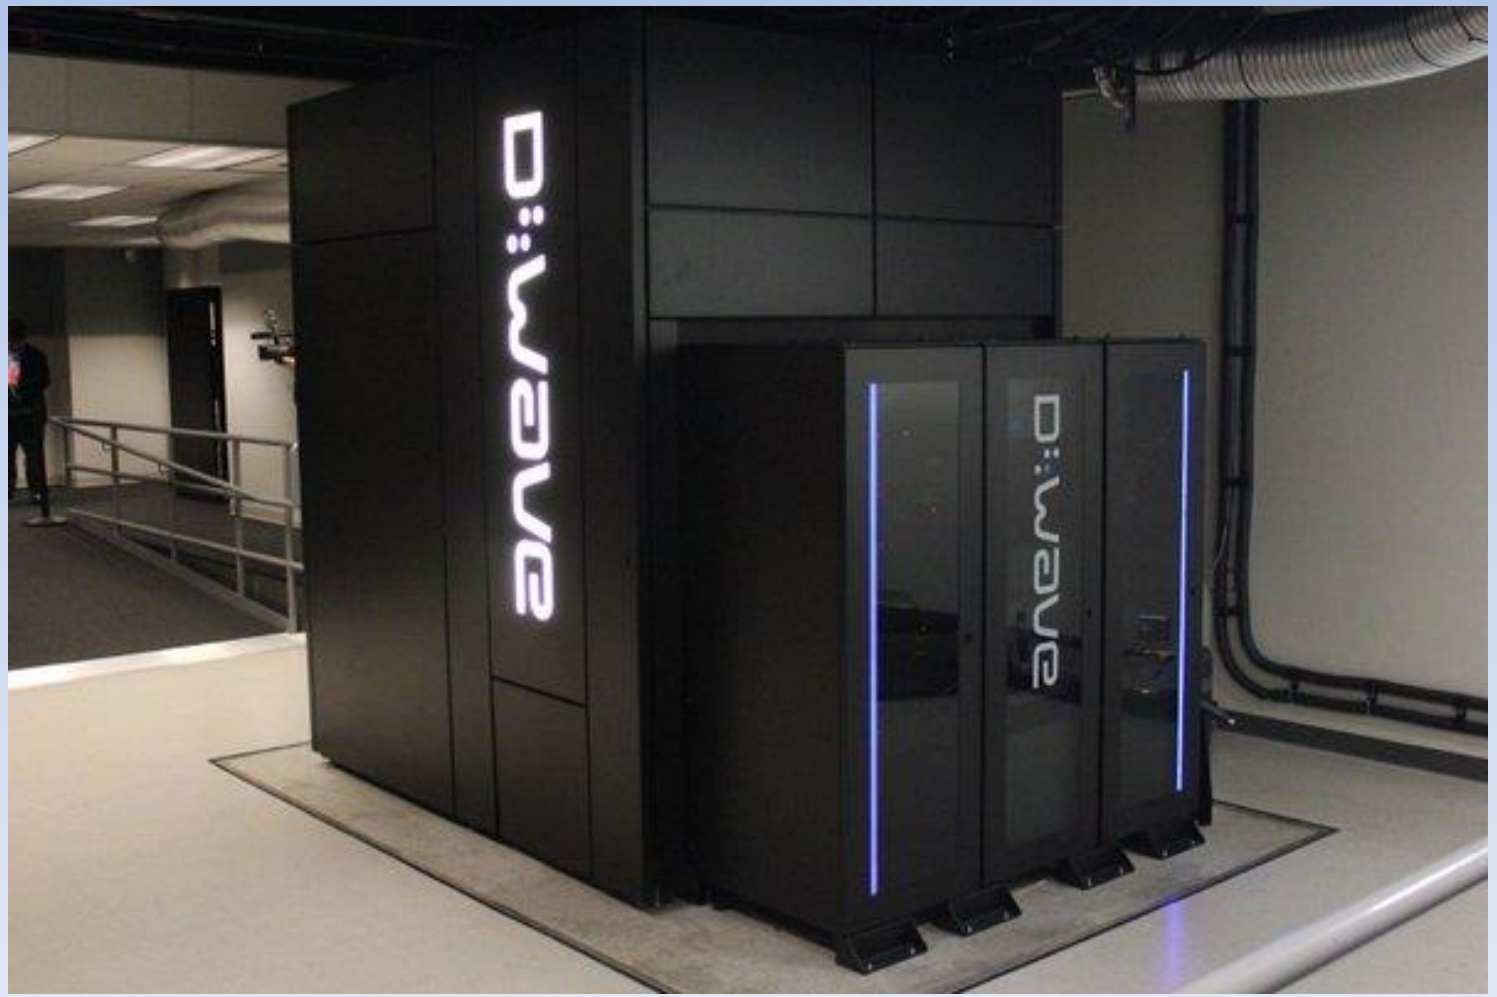
- This superposition of qubits is what gives quantum computers their inherent parallelism.
- This parallelism allows a quantum computer to work on a million computations at once, while desktop PC works on one.

Implementation

- Scientists have already built basic quantum computers that can perform certain calculations.



- At a NASA lab in Silicon Valley, Google is testing a D-Wave 2X quantum computer.

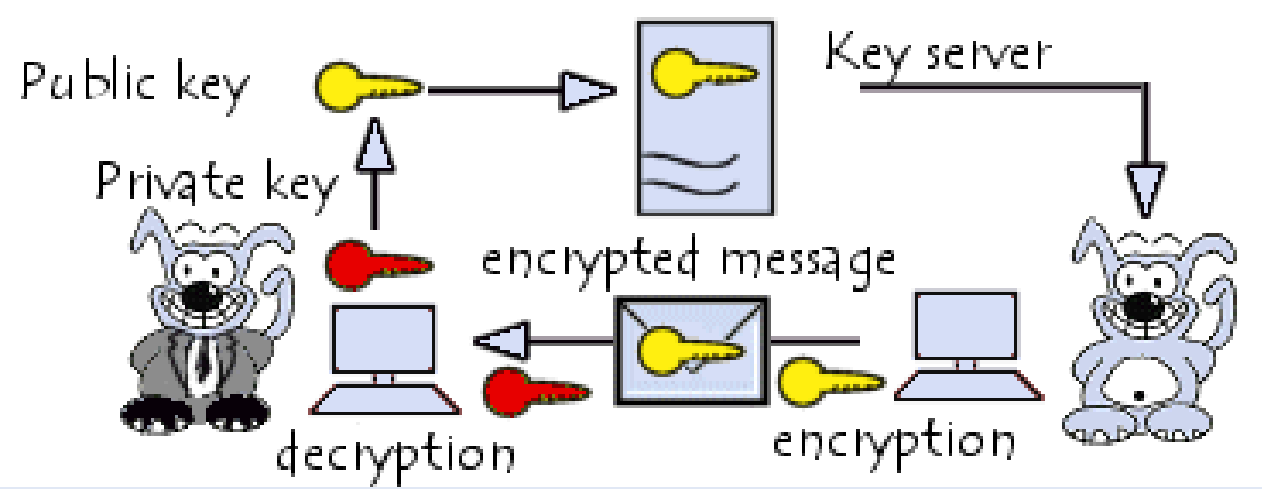


- In public-key cryptography, data is secured by math problems that are easy to solve, but hard to reverse engineer.
- While it is easy for a computer to multiply two prime numbers to produce a larger integer.

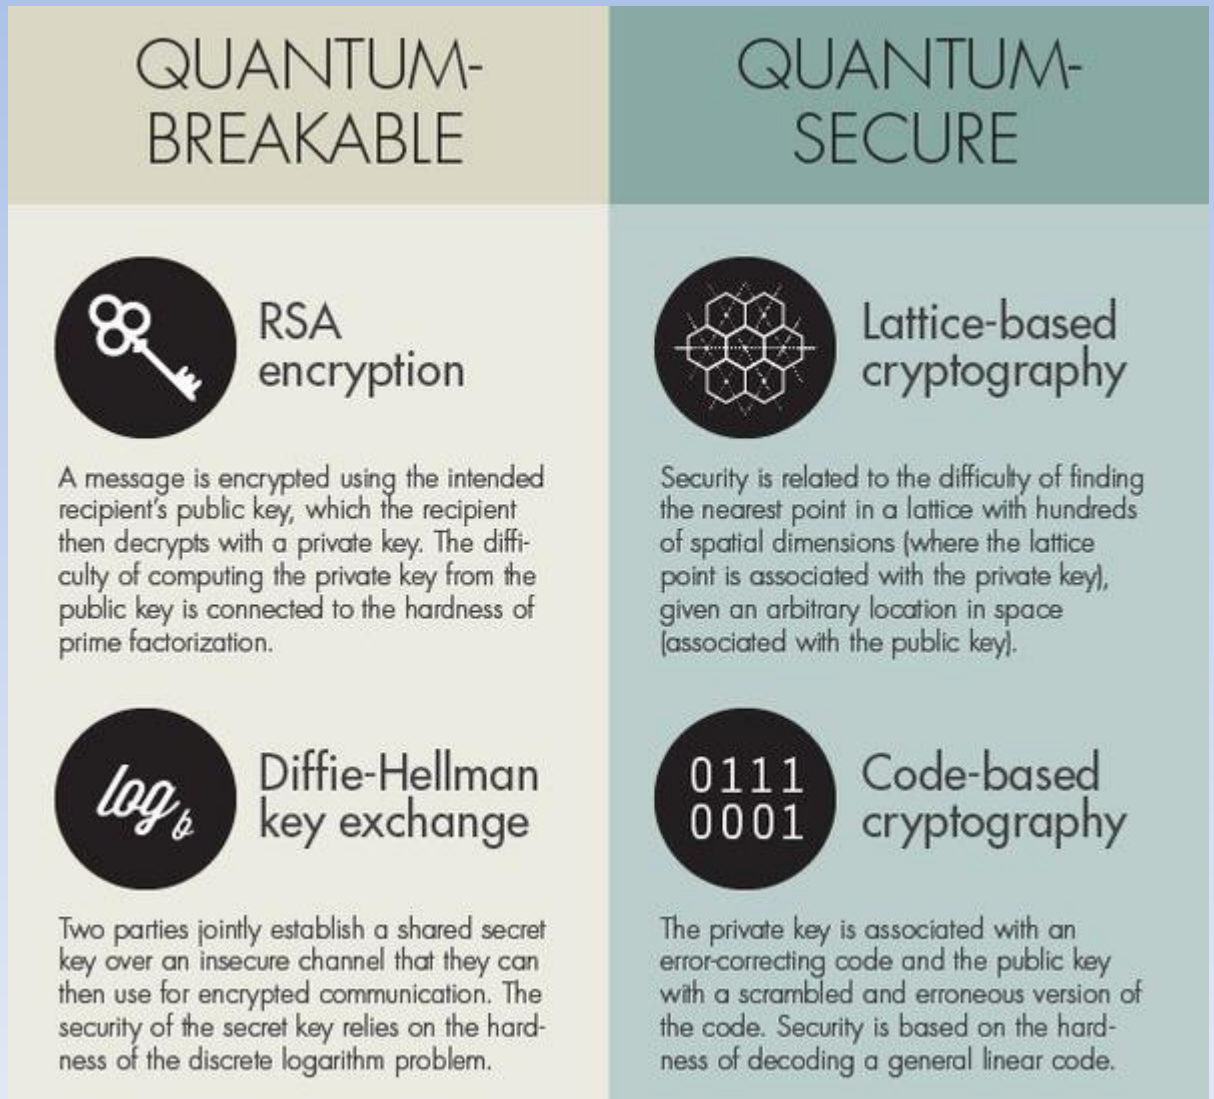
**34,141 x 81,749 = 2,790,992,609**

- It takes an impractically long time on a computer to factorize a large enough integer into its component primes.

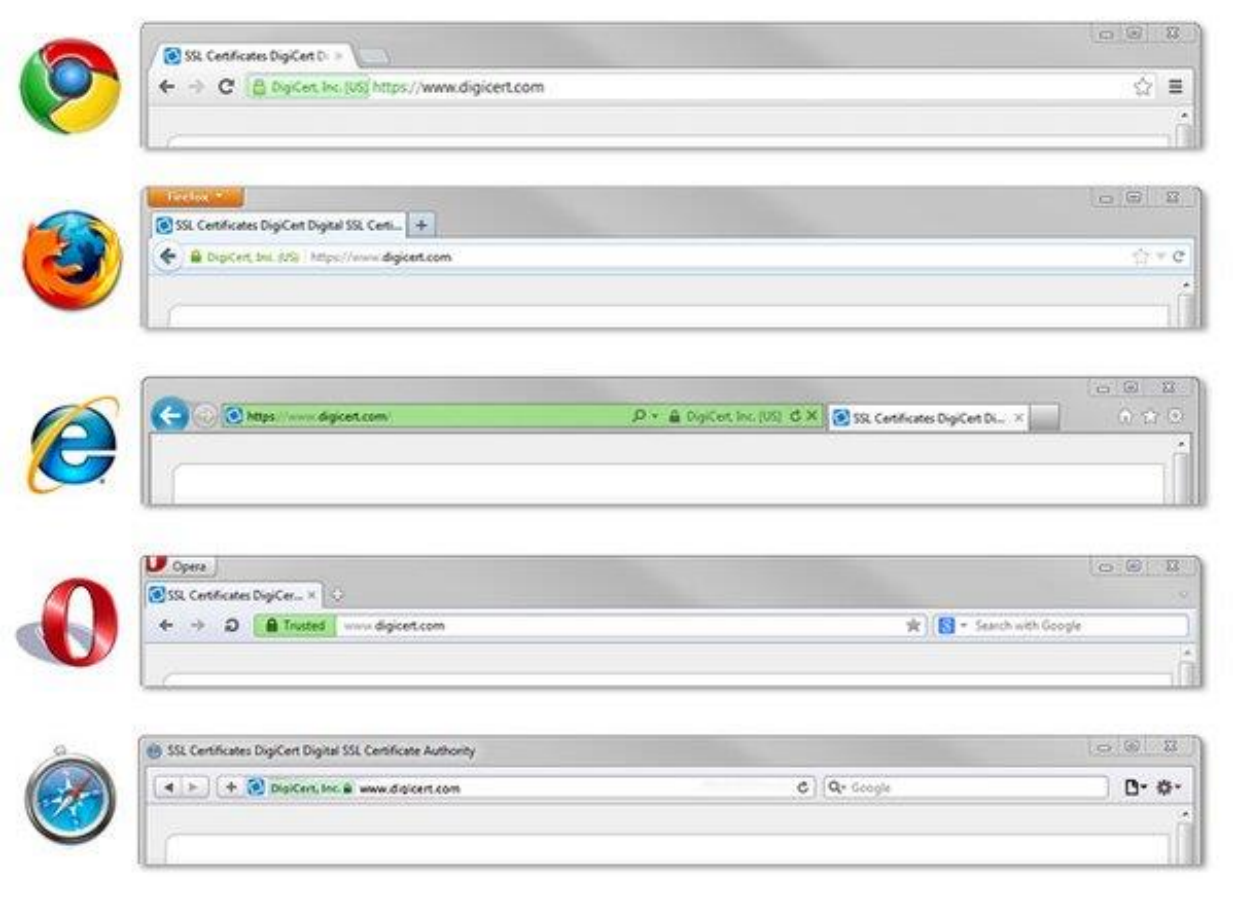
- In a crypto scheme based on prime factorization, the primes serve as a person's "private key," which is not shared.
- The product of the primes serves as the "public key," which is distributed publicly.
- When someone else uses the public key to encrypt a message, only the person in possession of the private key can decrypt it.



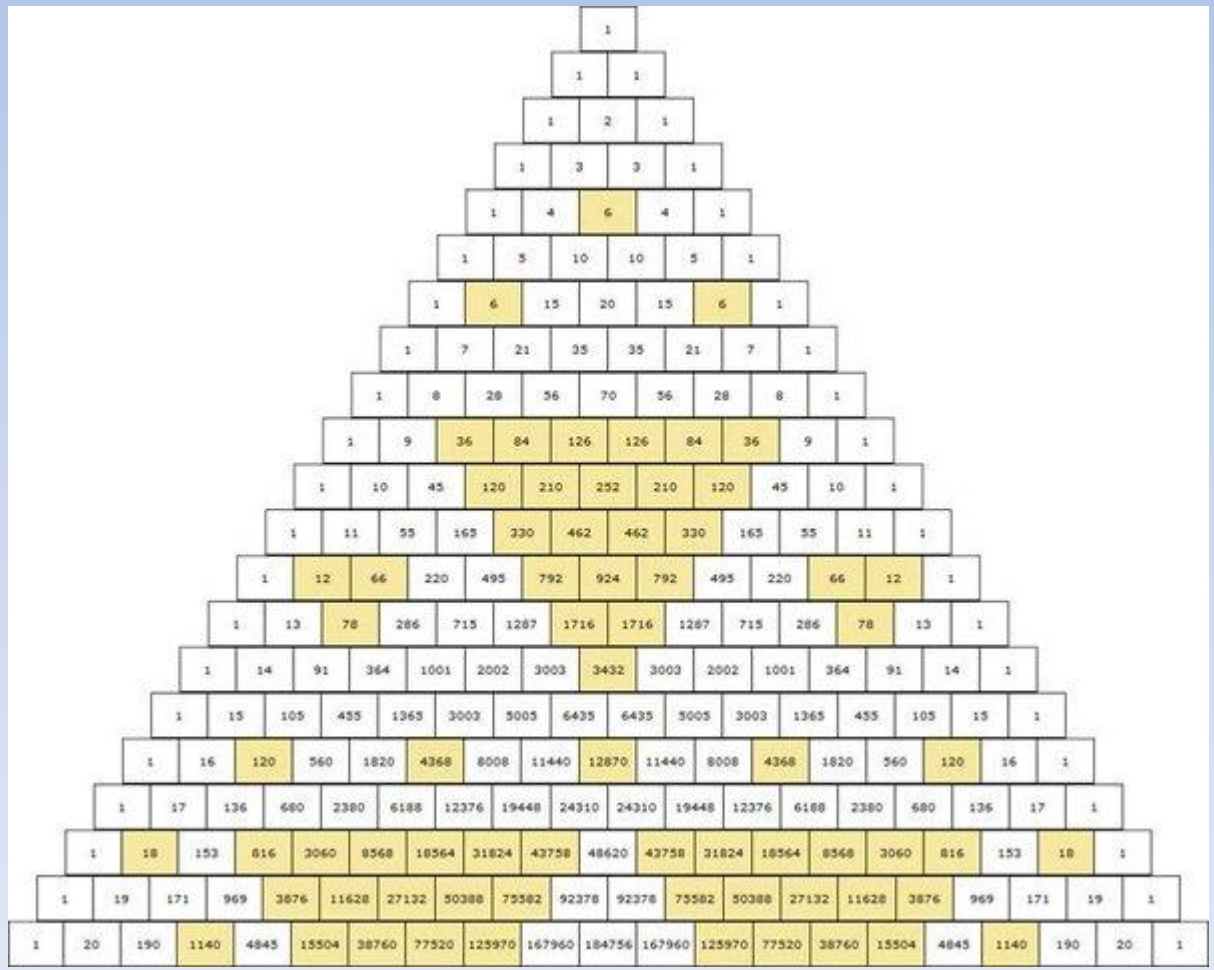
- Widely used today RSA and the Diffie-Hellman key exchange based on this principle.



- RSA(Rivest-Shamir-Adleman) algorithm is used in browsers which need to establish a secure connection.
- Every time you visit a website with a URL that begins “HTTPS,” that algorithm is used.



- A quantum computer could efficiently find prime factors for large integers.



- This ability would allow a quantum computer to decrypt many of the cryptographic systems in use today.

## Conclusion

- Quantum computing is still in early stages of development. But quantum computers will replace silicon chips in the future, just like the transistor once replaced the vacuum tube.
